Depth Frame I

get_depth() :

- It takes no input arguments.
- The depth frame is retrieved in mm and it is divided by a constant so that it falls in 0 to 255 range.
- The frame is passed through a filter and noise is eliminated.
- The return value is a $640 * 480$ matrix of depth frame.

Depth Frame II

filter_smooth() :

- It takes the original depth frame with noise
- It masks the noise pixels
- It is then passed through a filter to filter the noise.
- It is then passed through a bilateral filter for better results
- It returns the smoothened image of the frame

Depth Frame III

filter_noise() :

- It takes the original frame as input for processing. It takes noise mask and original frame with noise pixels made white. It takes the number of tiles in a row or a column
- The algorithm takes the mean of the frame in a particular tile and replaces the noise pixels with those values
- It returns the filtered noise depth frame

Robot Traversing I

regular_movement() :

- It takes no input arguments.
- The depth frame is divided in 8 regions.
- The for loop starts with the middlemost frames and goes sideways in both directions at a time.
- Whenever an object is detected in the range the function sends the number of the section in which it is detected
- If no object is detected in any of the divisions than the robot searches for the wall
- The robot follows the wall and maps the objects

Robot Traversing II

door_movement() :

- It takes no input arguments
- The frame is divided into 3 regions: left area, middlearea, rightarea.
- The mean of all the regions is taken.
- If the middleregions goes below the threshold than left and right area means are checked
- The region with higher mean is selected and robot turns in that direction as higher value indicates more depth
- So the robot traverses on the intuition of the area mean after door is detected

Robot Traversing III

doorway_movement() :

- It takes the midpoint of the width of the door edges as input
- If the point is left of the frame than robot turns left so it comes in between and vice versa
- The robot therefore orients themselves so that the door is in front of the robot

Robot Traversing IV

back_movement() :

- It takes depth map as input
- The depth frame is divided in three regions
- If the object comes in the blind spot of the Kinect than the robot will move back
- Here we have used the disadvantage of the blind spot of Kinect as an advantage because the Kinect cannot determine depth of object close to it and gives 255 value to those pixels
- If the number of white pixels crosses a threshold than the robot will move back

Robot Traversing V

stuck_pos_movement() :

- It takes no input arguments
- It calculates the mean of the left and right of the frame.
- The section with higher mean, the robot takes a left or right turn until it comes out of the stuck position
- This function basically moves the robot out of stuck position

Robot Traversing VI

search_wall() :

- It takes only the direction of the wall as input. 0 is left and 1 is right
- The robot takes a left or right until the left part of the frame or the right part falls in range of the Kinect

Dimension Calculation I

actual_height_in_mm() :

- The input arguments are the co-ordinates of the left top, left bottom, right top, right bottom points of the door
- The function creates a small 10x30 area and finds the minimum pixel value as that will be the depth value of that point
- So we get the depth distance of the four points.
- Now 640 pixels corresponds to 57 degrees and 480 pixels to 430 degrees. SO we find the pixels height to find the angle formed by the line joining the top and bottom points
- Using Cosine rule we find the height of the third side of the triangle formed by joining all the points.
- Rescaling the height we get the actual height of the left and right edges of the door
- It returns the left and right door edges

Dimension Calculation II

actual_width_in_mm() :

- The input arguments are the co-ordinates of the top and bottom of the left edge and the right edge, the midpoints of the contours of the left and right edges
- Using the co-ordinates we choose the area around the edges and using warp perspective we make it a rectangle
- We find the minimum of the matrix and find the depth of the left and right edges
- We select the left area for the left edge and right area for the right edge
- 640 pixels corresponds to 57 degrees so we find the pixel width using the centroid of the left and right edges
- Using the pixel width we find the angle between the two edges and using cosine rule we find the actual width of the door
- We return the actual width of the door from this function

Dimension Calculation III

`return_height_in_mm()` :

- The input arguments are the co-ordinates of the left top, left bottom, right top, right bottom points of the door
- The function creates a small 10x20 area and finds the minimum pixel value as that will be the depth value of that point
- So we get the depth distance of the four points.
- Now 640 pixels corresponds to 57 degrees and 480 pixels to 430 degrees. SO we find the pixels height to find the angle formed by the line joining the top and bottom points
- Using Pythagoras theorem we find the actual height of the edge of the door
- The assumption is that the depth of the bottom points is in line with the robot and the triangle formed is a right angled triangle
- Rescaling the height we get the actual height of the left and right edges of the door
- It returns the left and right door edges

Dimension Calculation IV

probability() :

- The input arguments are the standard value, the variance and the data for which we will find the probability of closeness to the standard value
- First we form a gaussian curve from the mean and the standard value
- The numbers are mapped to 0 to 100 for percentage probability.
- If the number falls in the range than a probability value is returned and if the value falls out of range it returns a zero probability

Left - Right Movements I

take_right() :

- It takes no input arguments
- The function finds the depth frame in a while loop and calculates the mean of the pixel values in the middle frame
- If the mean goes above threshold the robot moves forward and resumes its normal functioning
- The robot takes a right until the depth is more in the middle frame

Left - Right Movements II

take_left() :

- It takes no input arguments
- The function finds the depth frame in a while loop and calculates the mean of the pixel values in the middle frame
- If the mean goes above threshold the robot moves forward and resumes its normal functioning
- The robot takes a left until the depth is more in the middle frame

Left - Right Movements III

take_right_near() :

- It takes no input arguments
- The function finds the depth frame in a while loop and counts the number of pixels of the objects that fall in its range
- If the count goes below a threshold than the robot will move forward and resume its movement
- The robot takes a right until the objects go out of the Kinect sensor range which we specify

Left - Right Movements IV

take_left_near() :

- It takes no input arguments
- The function finds the depth frame in a while loop and counts the number of pixels of the objects that fall in its range
- If the count goes below a threshold than the robot will move forward and resume its movement
- The robot takes a left until the objects go out of the Kinect sensor range which we specify

Door tests I

actual_height_test() :

- It takes two arguments: The left edge height and the right edge height
- It returns the probability percentage of the edges to be door edge. We have sent 1.5m as standard value and 1500 is the variance
- The average of the two probabilities is returned from this function

Door tests II

actual_width_test() :

- It takes only one argument: the width of the edges
- It returns the probability of the width to be a door width. We have set 1m as the standard width and the variance is 1m
- The function returns the actual width between the two edges

Door tests III

rectangle_door_test() :

- We send the co-ordinates of the top and bottom edges of the left and right edges, left and right edges centroid, the co-ordinates of the left and right points of horizontal edge and the centroid of the edge
- We find the pixel width of the door using the three points of the left and right edges and find the error with the horizontal edge pixel length
- The error is probabilistic in three cases and we find the average of the three values
- The probability of horizontal edge being a door edge is returned

Door tests IV

is_door() :

- The arguments needed are the co-ordinates of the top and bottom points of the left and right edges and the centroids of those edges
- The pixel difference is calculated between the two pixel heights of the edges.
- The pixel difference between the centroids should be within range and the difference in door pixel heights should be in range
- The function returns a true or a false value based on the intuition of pixel measurements

Edges and lines I

contours_return() :

- The arguments are the depth array and the shift for detecting the edges
- The frame pixels are shifted by the number specified from the input argument
- The shifted frame is subtracted with the original so the difference in the pixels are stored as a frame
- The more difference is masked in the frame. The masked regions form a contour and thus contours are formed
- The function returns all the contours where depth difference is more

Edges and lines II

horizontal_lines() :

- The horizontal edge contours are detected by shifting the pixels by 6400 so that the frame is shifted 10 pixels down
- The horizontal edges are drawn for the contours and all the horizontal edges data are saved in corresponding lists
- the function returns the list of left and right point edge co-ordinates the centroid of the edge and the number of edges

Edges and lines III

left_right_lines() :

- The arguments are the left and right contours
- The function creates a list of co-ordinates of left and right edges in a list
- The data is stored only if the centroid value is not zero
- The function returns the list of all the values of co-ordinates of the left and right edges

Edges and lines IV

horizontal_edge() :

- Argument is a contour
- If the contour area crosses a threshold than its extreme points are deduced
- To ensure almost straight lines are selected as edges we find the pixel difference between the y co-ordinates of the top and bottom points
- If the difference is more than threshold than it is a potential edge.
- The pixel width is also calculated and if it crosses a threshold than the edge is a potential door edge
- The function returns the horizontal edges in the frame

Edges and lines V

potential_leftedge() :

- Argument is a contour
- If the contour area crosses a threshold than its extreme points are deduced
- To ensure almost straight lines are selected as edges we find the pixel difference between the x co-ordinates of the top and bottom points
- If the difference is more than threshold than it is a potential edge.
- The pixel height is also calculated and if it crosses a threshold than the edge is a potential door edge
- the right area of the edge is taken and using warping the mean of the area is found. If the mean is above threshold than it is potential left edge
- The function returns the co-ordinates of left edges in the frame

Edges and lines VI

potential_rightedge() :

- Argument is a contour
- If the contour area crosses a threshold than its extreme points are deduced
- To ensure almost straight lines are selected as edges we find the pixel difference between the x co-ordinates of the top and bottom points
- If the difference is more than threshold than it is a potential edge.
- The pixel height is also calculated and if it crosses a threshold than the edge is a potential door edge
- the left area of the edge is taken and using warping the mean of the area is found. If the mean is above threshold than it is potential right edge
- The function returns the co-ordinates of right edges in the frame

Communication and Pixel Count I

count_near_pixels() :

- Specifies the area and the distance threshold under which object should be detected
- The function masks the frame based on the depth distance given. for eg. If we give 1 m then it will display values only within that distance
- The visible pixel count is returned from the function

Communication and Pixel Count II

data_send() :

- the arguments are the modes of the left and right motor
- the mode selection is based on the division in which the object is detected
- Based on the mode selected a particular char value is send to the robot which sets the velocity of the two motors of the robot
- If the mode is 4,4 than the robot is stuck in a position and a function is called for that movement

Door Detection I

door_detection() :

- Left, right and horizontal lines are formed by the respective functions
- Probability of all the three tests are calculated and their weighted average is taken
- 50 percent to height 40 percent to width and 10 percent to the horizontal edge tests
- If the weighted sum crosses a certain threshold than the frame contains a door.
- The graph is plotted simultaneously with the data being given as input
- If the door is detected the flag is set to true and the buzzer gives a beeping sound

Door Detection II

start() :

- This function runs the actual code for door detection exit and algorithm
- The kinect is set to 20 degrees and initial frames are skipped
- The program runs after these steps and robot traverses the room and exits room from the door
